Abstract

Many important learning tasks feel uninteresting and tedious to learners. This research proposed that making such tasks meaningful by promoting a prosocial, self-transcendent purpose could improve academic self-regulation. This proposal was supported in four studies with over 2,000 adolescents and young adults. Study 1 documented a correlation between a self-transcendent purpose for learning and both trait and behavioral measures of academic self-regulation. Those with more of a purpose for learning persisted longer on a boring task rather than give in to a tempting alternative. Many months later, they were also more likely to remain in college. Study 2 addressed causality. It showed that a brief, one-time psychological intervention promoting a self-transcendent purpose for learning could improve high school science and math GPA over several months. Studies 3 and 4 were short-term experiments that explored possible mechanisms. They showed that the self-transcendent purpose manipulation could increase deeper learning behavior on tedious test review materials (Study 3), and sustain self-regulation over the course of an increasingly-boring task (Study 4). More self-oriented motives for learning—such as the desire to have an interesting or enjoyable career—did not consistently produce the same benefits (Studies 1 and 4).

Boring but Important:  
A Self-Transcendent Purpose for Learning  
Fosters Academic Self-Regulation

“It's only when you hitch your wagon to something larger than yourself that you realize your true potential and discover the role that you'll play in writing the next great chapter in the American story.”

- President Barack Obama,
Wesleyan University Commencement Speech, 2008

Many of the tasks that contribute most to the development of valuable skills are also, unfortunately, commonly experienced as tedious and unpleasant (Duckworth, Kirby, Tsukayama, Berstein, & Ericsson, 2010; also see Ericsson, 2006, 2007, 2009; Ericsson & Ward, 2007; Ericsson, Krampe, & Tesch-Romer, 1993). For example, skills in science, technology, engineering, and mathematics (STEM) are in high demand, and, according to some estimates, jobs in the STEM sector will grow by more than 20% in the next few decades (U.S. Congress Joint Economic Committee, 2012). Yet in a representative sample survey, over half of middle school students said they would rather eat broccoli than do their math homework; 44% would rather take out the trash (Raytheon Company, 2012).

To achieve longer-term aims, learners must sometimes regulate attention, emotion, and behavior in the face of tempting alternatives (Duckworth & Carlson, in press; Fujita, 2011; Mischel, Shoda, & Rodriguez, 1989). Indeed, individual differences in factors such as “grit” and self-control are predictive of eventual skill acquisition and expert performance, controlling for cognitive ability (Duckworth, Tsukayama, & Kirby, 2013; Duckworth, Peterson, Matthews, & Kelly, 2007; Moffitt et al., 2011). Where do these factors come from? Individuals are known to marshal self-discipline more when they are pursuing personally-meaningful goals (see Fishbach & Trope, 2005; Fishbach, Zhang, & Trope, 2010; Loewenstein, 1996; Mischel, Cantor, &

**Defining a “Purpose for Learning”**

People can have a variety of motives for learning. Learners may find a task intrinsically enjoyable, or believe that it will be useful for a personally-fulfilling career. Learners may also have motives that transcend self-interest. These may involve service to other individuals, to an ideal, to a social justice cause, or to a spiritual entity (Damon, Menon, & Bronk, 2003; Frankl, 1963; Koltko-Rivera, 2006; Schwartz, 1992; Maslow, 1969). Both of these types of motives—self-oriented and self-transcendent—can be important for learners. They can also co-exist (Batson, 1998; also see Feiler, Tost, & Grant, 2012). In fact, in a series of qualitative interviews conducted with a diverse group of high school adolescents, it was common for teens to pair self-transcendent motives with self-oriented motives—much more common in fact than only having a self-transcendent motive (Yeager & Bundick, 2009; Yeager et al., 2012).

In line with this, we define a “purpose for learning” as a goal that is motivated both by an opportunity to benefit the self and by the potential to have some effect on or connection to the world beyond the self (Yeager & Bundick, 2009; Yeager et al., 2012; see Burrow & Hill, 2011; Damon et al., 2003). Embedded in this definition is a focus on the motive or rationale for the goal (e.g., “helping people”) rather than on content of a goal (e.g. “being an engineer”). For example, a purpose for learning in a high school science class might be that a student would one day like to use the acquired knowledge to build bridges that help people (a self-transcendent
component). The same student might also believe that engineering would be a fulfilling, interesting, and enjoyable career (a self-oriented component). In the present research, we examine whether the combination of these two motives—that is, a purpose for learning—could produce benefits that self-oriented motives alone could not achieve.

**Purpose, Meaning and Persistence**

There is good reason to believe that a prosocial, self-transcendent purpose can promote the view that a task is personally meaningful (e.g., Grant, 2007, 2013; Olivola & Shafir, 2013; also see Duffy & Dik, 2009; Steger et al., 2008; Steger, 2012). A classic example comes from Viktor Frankl (1963). In writing about the psychology of surviving a concentration camp, he describes how a self-transcendent purpose in life creates a feeling that one’s actions are important for the world, empowering a person to persist even in the most appalling circumstances. He wrote “A [person] who becomes conscious of the responsibility he bears toward a human being who affectionately waits for him, or to an unfinished work, will never be able to throw away his life” (p. 80). Channeling Neitzche, Frankl states “He knows the ‘why’ for his existence and will be able to bear almost any ‘how’” (1963, p. 80). Support for this idea also comes from observational research of people working in “dirty” jobs—jobs with low-status and requiring extremely repetitive tasks (e.g., trash men, hospital orderlies, prison guards). Individuals with these jobs find their work more meaningful and carry it out more effectively when they focus on the benefit of these tasks for helping others or society at large (Ashforth & Kreiner, 1999; Hughes, 1958, 1962; also see Dutton, Roberts, & Bednar, 2010; Wrzesniewski, 1995).

---

1 A purpose is distinct from but related to personal meaning. The former includes a person’s goal and his or her motives for pursuing it. The latter refers to the sense that something matters and makes sense in the context of one’s life or worldview (Steger, Kashdan, & Oishi, 2008; Yeager & Bundick, 2009).
Dutton, & Debebe, 2003; cf. Olivola & Shafir, 2013). Altogether, highly aversive experiences may become more bearable when they are viewed as having positive consequences that transcend the self.

More directly relevant is research with adolescents in high school. Yeager et al. (2012) found that some high school-aged adolescents spontaneously generated a purpose for learning during interviews, meaning that they talked about both a self-transcendent motive and an intrinsic, self-oriented motive for their future work (e.g., being a doctor to help people and because it would be an enjoyable career). Students with a purpose rated their schoolwork in general as more personally meaningful than adolescents with no career goal or only extrinsic motives, even at a two-year follow-up. Other high school students discussed only typical interest-based, self-oriented motives. The latter group of students rated their schoolwork as no more meaningful compared to students with no future work goals or only extrinsic motives such as making money (Yeager et al., 2012). However, this study was limited in that it did not directly assess perceptions of tedious, skill-building tasks nor did it assess behavior. Instead Yeager et al. (2012) focused on global evaluations of the meaningfulness of school in general. This past research also did not address causality with experimental designs. These limitations are addressed in the present research.

Some past experiments have linked prosocial, self-transcendent motives to persistence on tasks at work, not school. For example, telemarketers raised more money when they were asked to focus on the benefits of their efforts for poor children, while medical professionals were more likely to stop and wash their hands when they focused on others’ health, compared to those who focused on personal benefits (Grant, 2008; Grant & Hoffman, 2011; also see Feiler et al., 2012; for findings from other workplaces see, Grant & Rothbard, in press; cf. Sansone, Weir, Harpster,
A PURPOSE FOR LEARNING

& Morgan, 1992). Note that the theoretical basis for these findings is that a self-transcendent motive makes aversive experiences more bearable, not more enjoyable. Prosocial motives diminish the correlation between feeling bad during a task and the reduced motivation to complete it (Grant & Sonnentag, 2010; also see Grant & Campbell, 2007).

For the most part, past experimental research has not sought to understand the effects of a self-transcendent purpose in the context of basic, foundational skills that facilitate the later acquisition of more clearly useful skills. Past studies investigated, for instance, raising money for poor children (Grant, 2008; also see Dunn, Aknin, & Nortin, 2008) or preventing infection (Grant & Hoffman, 2011). It is easy to see how these actions help others. But when high school students engage in a learning task such as factoring trinomials in Algebra, or balancing stoichiometric equations in Chemistry, it can be difficult to see the steps through which deeply learning from these tasks can help them benefit others. That is, raising money for poor people is directly prosocial, but learning fractions must be construed as such.

The present research will test whether students with more of a self-transcendent purpose for learning can show greater persistence even on tedious learning activities that provide a foundation for uncertain future contributions to the world beyond the self. Some past research has found that providing intrinsic vs. extrinsic motives for learning tasks (e.g., becoming healthy vs. looking physically attractive) can lead to greater task persistence and deeper processing of information (e.g., Vansteenkiste, Simons, Lens, Sheldon, & Deci, 2004; also see Jang, 2008; for a review, see Vansteenkiste et al., 2006 or Patall, Cooper, & Robinson, 2008). Similarly, some research has found that asking students to generate reasons why a learning task could be relevant to their goals could improve course performance among low-performers (Hulleman & Harackiewicz, 2009). These studies were foundational to the present research. However they
A PURPOSE FOR LEARNING

have not distinguished the intended beneficiary of the learning—the self versus something that transgresses the self—as the present research seeks to do.

In addition, past studies have focused on motives for completing a given task—for instance, learning about correlation coefficients to interpret education research (Jang, 2008), or completing the week’s science class objectives to help out on the farm (Hulleman & Harackiewicz, 2009). However, an important skill for self-regulation is to abstract up a level to one’s motives for being involved in an educational enterprise more generally—e.g., “science” or “math” or even “school.” This is important because many times in daily life it is uncertain whether or how one will use the knowledge gained from a given learning objective or task. Indeed, teachers very rarely provide any rationale for mastering a learning objective (Stipek, 2004), let alone a self-transcendent one. This is especially true in STEM courses (Carnevale & Desrochers, 2003; also see Diekman, Clark, Johnston, Brown, & Steinberg, 2011). In these instances it may be important to reconstrue a foundational task—such as practicing math facts—more generally in terms of their relation to one’s broader, self-transcendent motives for working hard in school.

The Present Research

Four studies investigated the hypothesis that a self-transcendent purpose for learning would promote academic self-regulation. In Study 1 we hypothesized that a self-transcendent purpose for learning would be correlated with indicators of academic self-regulation both at the trait level (self-reported grit and self-control) and at the behavioral level (short-term persistence on a boring math task and longitudinal persistence in college). We further hypothesized that these relations would be found above and beyond the effects of more intrinsic, self-oriented motives (e.g., following one’s intellectual interests).
Study 2 examined a possible causal effect of a self-transcendent purpose for learning. In order to do so it was necessary to create an exercise to adjust adolescents’ purposes for learning, which past research has not been able to do (cf. Dik, Steger, Gibson, & Peisner, 2011). Indeed, a purpose is likely to be highly personal and represent the product of a large number of influences in life, including teachers, parents, friends and the media (e.g., Damon, 2008; Moran, Bundick, Malin, & Reilly, 2013; Steger, Bundick, & Yeager, 2012), perhaps making it difficult to manipulate. Yet advances have been made in recent years in the optimal design of psychological interventions in educational settings (e.g., Blackwell, Trzesniewski, & Dweck, 2007; Cohen & Sherman, 2014; Cohen & Garcia, 2012; Hulleman & Harackiewicz, 2009; Walton & Cohen, 2011; also see Wilson & Linville, 1982). We were informed by these. We hypothesized that a novel self-transcendent purpose for learning intervention—one that employed the insights from past successful interventions—could improve grades in subject areas likely to be seen as tedious, such as high school math and science classes.

Studies 3 and 4 examined potential mechanisms for the results of Studies 1 and 2. Specifically, Study 3 examined effects of the novel intervention on behavior on a shorter time-course, testing the hypothesis that a self-transcendent purpose for learning could lead students to learn more deeply from an immediate, real-world academic task. Study 4 sought to isolate the effect of a purpose for learning manipulation on self-regulation more precisely by administering a dependent measure that pitted a boring math activity directly against tempting alternatives.

**Study 1: An Initial Correlational Investigation**

Study 1 was a correlational study among a low socioeconomic status (SES) group of high school seniors. Based on prior research, they might have significant difficulty regulating immediate motivations in the service of long-term goals (Evans & Rosenbaum, 2008; Vohs,
We hypothesized that in this population a self-transcendent purpose would correlate with indicators of self-discipline—both self-reported and behavioral—assessed at the same measurement time. We further hypothesized that, in a multiple regression controlling for more self-oriented motives—even intrinsic interest-focused ones—a purpose for learning would continue to predict greater success at self-regulation.

We also examined longitudinal relations with goal persistence. This was done by collecting data on whether students were enrolled in college in the Fall semester following high school graduation, as they intended to do. Low-income students of color more commonly drop out of the college pipeline in the summer after college or during their first Fall semester, even when they have successfully graduated high school and been admitted to a college of their choice (Ryu, 2012). We hypothesized that a self-transcendent purpose would predict college persistence over time—a potential indicator of successfully regulating competing demands for time and attention in this low-income population. We also hypothesized that this relation would be found when controlling for self-oriented motives in a multiple regression.

Method

Participants. Participants were $N = 1,364$ seniors in their final semester at one of 10 participating urban public high schools (eight charters and two district schools). Ninety-nine percent said that they had applied for college and were planning on attending college in the Fall semester. They were located in Los Angeles, CA, Oakland, CA, New York City, NY, Austin, TX, Houston, TX, or Little Rock, AR. They were from low socio-economic backgrounds: over 90% received free or reduced-price lunch, a measure of low socio-economic status, and only 9% had one parent who had completed a 2 or 4-year degree; by contrast, 25% of parents did not have a high school diploma. The sample overall was nearly evenly split on gender (57% female), and
had a large proportion of students that are typically under-represented in higher education in the U.S., 38% African American, 48% Hispanic / Latino, 5% Asian, 4% White. Some participants did not provide data on some measures, and so degrees of freedom varied across analyses. No other participants were excluded from analyses. There was no stopping rule for data collection because all college-going students in each school were invited to participate.

Procedures. Participants completed a web-based survey in the school’s computer lab during the school day in the Spring semester (February to May) of senior year. Teachers directed students to a website (www.perts.net) that delivered the survey session, which lasted one class period. Many months later, toward the end of what was the Fall semester for students in college, college persistence data were collected from the National Student Clearinghouse (NSC).

Measures

Motives for going to college. The primary predictor variables were self-transcendent motives, intrinsic self-oriented motives, and extrinsic self-oriented motives. The preface for the items assessing these motives was: “How true for you personally are each of the following reasons for going to college?” Each was rated on a five-point scale (Response options: Not at all true, Slightly true, Somewhat true, Very true, Completely true) and coded to range from 1 to 5, with 5 corresponding to greater endorsement.

Self-transcendent motives (purpose for learning). We averaged across the following three items to assess students’ self-transcendent motives for going to college (a purpose for learning), operationalized as a personally-relevant desire to learn in order to make a contribution to the world beyond the self: “I want to learn things that will help me make a positive impact on the world,” “I want to gain skills that I can use in a job that help others,” and “I want to become an educated citizen that can contribute to society” (α = .75).
**Self-oriented motives.** We averaged across the following three items adapted from Stephens et al.’s (2012) assessment of self-oriented, interest-driven motives for going to college: “I want to expand my knowledge of the world,” “I want to become an independent thinker,” and “I want to learn more about my interests” (α = .70). Note that these are still personal-important intrinsic motives for learning, and might be expected to predict greater self-regulation, thus providing a high standard of comparison for the self-transcendent motives.

**Extrinsic motives.** Finally, we measured typical extrinsic, self-oriented motives for going to college: “I want to get a good job,” “I want to leave my parents’ house,” “I want to earn more money,” and “I want to have fun and make new friends.” We wrote these items in collaboration with college counselors at the participating high schools. They were designed to reflect the counselors’ perceptions of why students want to go to college. Although the internal consistency reliability for these items was somewhat low (α = .50), they were face-valid. Below we show that a composite of these items produced relations with each of the constructs measured that replicates past research (Lee, McInerney, Liem, & Ortiga, 2010), supporting the validity of the composite despite low internal consistency. The same findings emerged when analyzing these items separately.

**Meaningfulness of schoolwork.** To assess individual differences in the meaningfulness of everyday academic tasks, we adapted a measure commonly used in research on action-identification theory: the Behavioral Identification Form (BIF; Vallacher & Wegner, 1989). The standard BIF asks participants to view a task and choose a description of it that either aligns with personally-meaningful values or goals, or with concrete actions required to complete the task. In the present research, we treat the choice of the former, more goal-directed description as an indication that a person is viewing it more meaningfully. Indeed, Michaels, Parkin and Vallacher
(2013) stated “people take meaning from their goals and values rather than the details of their actions” (p. 109).

We created a four-item version of the BIF that was tailored to assess whether students chronically make meaning out of boring and uninteresting everyday academic tasks in high school. See Figure 1 for an example. The measure presented participants with a description of each behavior, accompanied by a picture, and asked participants to select which of two action identifications best matched how they thought about the behavior. The four behaviors were “Taking the SAT,” “Doing your math homework,” “Writing an essay,” and “Using a planner to record upcoming tasks” (for pictures and response options, see the online supplement). In pre-testing focus groups with high school students, all four behaviors were evaluated as very tedious and very common. For each of the behaviors, (e.g., taking the SAT), we asked students whether a more concrete, lower-level statement (a description that emphasizes the means by which the action is performed, e.g., “Filling out bubbles on the SAT”) or a more goal-directed, personally-meaningful statement (a description emphasizing the meaning the action can have for a person’s pursuits in life, e.g., “Taking steps toward a college degree”) best described that behavior. The latter was our operationalization of whether the task was seen as more personally-meaningful. We summed across the items, so that higher values corresponded to a greater tendency to see schoolwork as meaningful (Range: 0 to 4).²

**Grit scale.** Participants completed an abbreviated version of the validated grit scale (Duckworth & Quinn, 2009), a measure that signals strong self-regulation in a number of past

---

² Pilot research confirmed that the present measure indicated greater personal meaning as expected by theory (Michaels, Parkin, & Vallacher, 2013). In a pilot survey with \( N = 151 \) high school students, our measure correlated with the presence of meaning in life scale (e.g., “I have a good sense of what makes my life meaningful;” Steger, Frazier, Oishi, & Kaler, 2006) at \( r = .30, p < .001 \).
A PURPOSE FOR LEARNING

studies. The scale asks: “I finish whatever I begin,” “I work very hard. I keep working when others stop to take a break,” “I stay interested in my goals, even if they take a long time (months or years) to complete,” and “I am diligent. I never give up.” Participants answered all items on 5-point fully-labeled scales (Response options: Not at all like me, Not much like me, Somewhat like me, Mostly like me, Very much like me). We averaged across the responses, with higher values corresponding to higher levels of grit (α = .78).

**Self-control scale.** Participants completed a validated measure of self-control when completing academic work (Tsukayama, Duckworth, & Kim, in press; Patrick & Duckworth, 2013). Items were: “I come to class prepared,” “I pay attention and resist distractions in class,” “I remember and follow directions,” and, “I get to work right away rather than procrastinating” (Response options: Not at all like me, Not much like me, Somewhat like me, Mostly like me, Very much like me). We averaged across these items, with higher values corresponding to greater academic self-control, (α = .71). Past research has shown that these items are correlated with other measures of self-regulation (such as grit, e.g. Table 1) but demonstrate divergent validity from them (Duckworth et al., 2007).

**The “diligence task:” A behavioral measure of academic self-regulation.** At the end of the survey, participants completed a novel standardized behavioral measure of self-regulation, called “the diligence task” (Galla et al., 2014). This task was designed to mirror the real-world choices students confront when completing homework and being tempted by the distractions of the digital age. Specifically, this task involved the choice of completing boring math problems (single-digit subtraction) or consuming captivating but time-wasting media (watching one or several entertaining, brief, viral videos [lasting 20-60 seconds] or playing the video game Tetris). At any time, participants could click on the left side of the screen and complete math problems
A PURPOSE FOR LEARNING

(“Do Math”) or click on the right side of the screen and consume media (“Play game or watch movie”). Participants were told there were no negative consequences for their choices and that they could do whatever they preferred. See Figure 2. The software (unknown to the participant) tracked the number of math problems completed successfully, producing our focal dependent measure.

To make the math problems potentially meaningful in students’ eyes—and worth completing—we told participants that successfully completing the tasks could possibly help them sharpen their math skills and stay prepared for their future careers. As a part of this cover story, we presented participants with summaries of actual scientific studies showing that increasingly as people rely on technology to do simple tasks, their grasp of basic skills can atrophy. As a result, all participants could plausibly see the successful completion of boring math problems as preparatory for a future career, if they so desired.

The task itself involved three blocks. Block 0 was a warm-up block to become familiar with the layout of the task. It involved a brief (1 minute) set of math problems, but without the option to play videos or video games. It will not be discussed further. Blocks 1 and 2 lasted four minutes each and involved the key behavioral choice: toggling between the math problems and the media (videos or Tetris). See Figure 2. We totaled the number of correct math responses in each block. In a separate validation study, five blocks were administered and boredom was assessed after each. A large increase in self-reported boredom occurred between the first block and the second, a significant difference, \( t(1019) = 4.69, p < .001 \), and boredom appeared to level-off after that. Therefore in the present study, values from Block 2, the more boring of the two
blocks, were used in analyses. The same overall pattern of results and level of statistical significance was found when Blocks 1 and 2 were averaged and analyzed as a single metric.\(^3\)

Finally, to ensure that the task elicited boredom as expected, one question assessed boredom on the math problems, immediately after Block 2: “How bored were you when working on the math problems?” (Response options: *Not bored at all, A little bored, Somewhat bored, Very bored, Extremely bored*; scoring: 1-5).

**College persistence.** College enrollment data were obtained from the National Student Clearinghouse (NSC), which is a non-profit database that reports on students receiving financial aid to both private and federal loan providers (Dynarski et al., 2013). Colleges submit student names to this database, and so it allows for objective, longitudinal assessment of student behavior with little or no missing data. In the present study, a value of 1 indicates that students were still enrolled at a four-year college during the Fall of 2013 after the “census date” (the date after which students owe tuition, normally 4-8 weeks into the term). A value of 0 means that they did not have an official enrollment value in the database at that time. Possible reasons for not being enrolled in the Fall include students who were admitted to a college but did not ever

---

\(^3\) There were some missing data for Block 2 because some participants (10%) did not even begin the block and instead waited for the browser to advance, without playing games or watching videos. Reports from teachers administering the task suggested that this was likely because students found Block 1 so aversive that they gave up on the task. Thus rather than treating these participants’ performance on Block 2 as missing data—effectively dropping participants—they were instead coded as having completed zero problems. We found that doing this and retaining all participants for analysis did not sacrifice validity—for instance, the correlation of boring math problems solved and self-reported trait self-control was \(r = .15, p<.001\), both when we counted these students’ Block 2 performance as missing data and when we counted the students as having completed zero problems. All conclusions about the significance of the predictors of diligence task data remained the same in both cases.
appear at their college in the Fall, or students who appeared at their college but withdrew during the semester.⁴

Initial analyses support the interpretation that college persistence was indeed meaningfully supported by individual differences in success at self-regulation. The number of boring math problems solved during the diligence task positively predicted college persistence six to ten months later, \( OR = 1.006, Z = 4.05, p < .001 \) (\( r = .14 \)), and the number of tempting videos or games consumed negatively did so, \( OR = .91, Z = 2.09, p = .036 \) (\( r = -.08 \)). This was true even controlling for cognitive ability (measure described below). Thus college persistence was an informative variable for assessing theory regarding self-regulation.

**Cognitive ability.** To rule out the alternative hypothesis that observed correlations between variables were due to shared variance in cognitive ability, we administered a brief (10-item) set of moderately-challenging problems from Raven’s progressive matrices (Raven, Raven, & Court, 1998). We used a sub-set of items rather than the full battery due to time limitations in the school setting. Although brief, this set of items showed substantial convergent validity with other measures of cognitive ability in a validation study that administered additional IQ measures to a sub-sample of the present study’s participants (see online supplement).

**Results**

---

⁴ The large majority of students said that their goal was to attend and graduate from a four-year college (85%), while the remaining students said their goal was to attend a two-year college. Interestingly, many students who said in May they would attend a two-year college ended up at a four-year college in the Fall, and so, to be conservative, our primary analyses included all participants regardless of their stated goal during senior year. However, we conducted supplementary analyses of the college persistence outcomes that were limited only to the sub-group who said they were planning on attending a four-year college. The significance tests for the focal variables were no different.
Our primary hypothesis was that a greater endorsement of self-transcendent motives for going to college would predict 1) the tendency to view tedious academic tasks in a more personally-meaningful fashion, and 2) the tendency to display greater academic self-regulation. Analyses focus first on the concurrently-measured variables, followed by the analysis of the longitudinal behavioral outcome: college persistence. Our secondary hypothesis was whether individual differences in the endorsement of the self-oriented motives showed the same pattern as the self-transcendent motives.

**Concurrent measures.** When inspecting zero-order correlations (Table 1), students who reported more of a self-transcendent purpose for learning also scored higher on the meaningfulness of schoolwork measure, $r = .23, p < .001$, conceptually replicating past research (Yeager & Bundick, 2009) but with a novel and more theoretically-precise measure. A self-transcendent purpose for learning also predicted more grit, $r = .39, p < .001$, more academic self-control, $r = .33, p < .001$, and a greater number of boring math problems solved in the face of tempting media, $r = .09, p < .01$.

Supplementary analyses of survey questions asked after the diligence task help clarify those results. Students who endorsed a self-transcendent purpose for learning did not perceive the single-digit subtraction problems as less boring, $r = -.02, p = .47$. Furthermore, 91% of participants reported at least some boredom, and 72% were “Extremely,” “Very,” or “Somewhat” bored. Thus the task was indeed boring. Yet those with more of a purpose solved somewhat more math problems despite the boredom (also see Grant & Sonnentag, 2010).

These correlations were maintained when controlling for potential confounding variables in a multiple regression: self-oriented, intrinsic motives for learning (e.g., exploring your interests), extrinsic motives for going to college (e.g., making more money), as well as sex, race
and ethnicity, and cognitive ability. Regression models are shown in Table 2. Inspecting the standardized regression coefficients in Table 2 shows that a self-transcendent purpose for learning predicted greater personal meaningfulness of schoolwork, $\beta = .15, p < .001$, grit, $\beta = .27, p < .001$, academic self-control, $\beta = .29, p < .001$, and the number of correctly-solved boring math problems, $\beta = .09, p = .01$. In this multiple regression, a self-oriented, intrinsic motive for learning did not significantly predict number of math problems solved (see row 2 in Table 2). It was a significantly weaker predictor of reported grit and self-control compared to a purpose for learning, Wald test of equality of coefficients, $F(1,1349) = 4.74, p = .03$.

Note that this analysis does not show that self-oriented motives are unimportant. Nearly all participants who reported at least some self-transcendent motives (e.g., at or above the scale midpoint) also expressed at least modest levels of intrinsic, self-oriented motives (also at or above the scale midpoint; also see Yeager et al. 2012). Nevertheless, more strongly endorsing a self-oriented motive was not related to individual differences self-regulation. By contrast, in a sample of adolescents with at least some level of self-oriented motivation, greater endorsement of self-transcendent motives more consistently predicted greater self-regulation.

Finally, zero-order correlations showed that intuitively appealing extrinsic motives such as making money in a future job were significant positive predictors of meaningfulness of schoolwork and trait-level self-regulation (Table 1). However this appeared to be due to shared variance with the other motives. The self-oriented items include variance both due to a general motivation to go to college—which would be shared with the purpose items—as well as variance due to more specific extrinsic motives (making money, getting out of the house), which might not be. In regression analyses that presumably remove the former source of variance, extrinsic motives were in every case strong negative predictors of both personal meaningfulness of
schoolwork and academic self-regulation (see row 3 in Table 2). That is, wanting to go to college in order to make money or get out of the house predicted worse academic self-regulation, net of the overall motivation to go to college.

**Longitudinal measure: college persistence.** Many factors are likely to affect whether high-school graduates follow through with their college aspirations. These include academic preparation or the need for financial aid. Yet students also face barriers that require self-regulation, such as bureaucratic difficulties of navigating the paperwork of enrollment, housing, course and major selection, etc., as well as the need to take entry-level, sometimes-tedious or disconnected introductory courses (Ryu, 2012). College students also have more freedom with their time as compared to high school students, and they must freely choose to work in service of their long-term goals even as they face daily temptations to engage in social activities or consume entertaining media. Because self-regulation appears to promote college persistence (recall that diligence task behavior predicted college enrollment), we hypothesized that a purpose for learning might predict goal persistence across the socially, academically, and bureaucratically-difficult transition to college.

Consistent with this speculation, in a logistic regression with no covariates, a self-transcendent purpose for learning significantly predicted college enrollment, *Odds Ratio (OR) = 1.40, Z = 4.82, p < .001*. Controlling for sex, race and ethnicity, cognitive ability, as well as cumulative high school grade point average (GPA), did not diminish this relation, *OR = 1.40, Z = 4.62, p < .001*. Estimated values from this model are depicted in Figure 3. This figure shows that for students with responses at the bottom of the purpose scale (the lowest two out of five points), only 30% of students were actively enrolled at college in the Fall immediately following high school graduation. Among students at the mid-point of the purpose scale, 57% were
enrolled in college. For students at the highest two out of five scale points, this number was even greater: 64%.\textsuperscript{5}

Finally, controlling for self-oriented, intrinsic motives for learning as well as extrinsic motives for going to college did not diminish the significant relation between a purpose for learning and college enrollment, \( OR = 1.34, Z = 2.77, p = .006 \). These additional motives did not significantly predict college enrollment: self-oriented, intrinsic motives (\( OR = 1.10, Z = .85, p = .40 \)) and extrinsic motives (\( OR = 1.11, Z = 1.05, p = .30 \)). Wald tests comparing the sizes of these coefficients to a self-transcendent purpose for learning failed to reach statistical significance (\( ps = .35 \) and .22, respectively). Altogether, a self-transcendent purpose for learning predicted persistence toward the eventual goal of college graduation. Other, more self-oriented motives did not, in the full regression model.

**Discussion**

This research was conducted with a large sample of low-income, mostly racial minority students, many of whom would be the first in their families to graduate from college. In this sample, those who expressed more of a self-transcendent purpose for learning also viewed tedious activities as more personally-meaningful and both reported and behaviorally displayed greater academic self-regulation. They were also more likely to continue toward their stated goal of persisting in college. These effects were independent of cognitive ability. In addition,

\textsuperscript{5} The relation was not exclusively driven by the low-purpose individuals. When re-conducting analyses only with the sample at or above the midpoint of the purpose scale (3, 4 or 5, excluding 1 and 2; see Figure 3), a self-transcendent purpose for learning remained a significant predictor of college enrollment, \( OR = 1.32, Z = 2.77, p = .006 \).
\textsuperscript{6} For a subset of students, we were able to obtain college-admissions test scores (SATs and ACTs). When re-conducting analyses with test scores as covariates, all conclusions about the significance of each of the motives (self-oriented and self-transcendent) were unchanged (\( ps < .05 \)).
stronger endorsement of more typical self-oriented motives did not as consistently predict greater self-regulation, suggesting that there is a unique contribution of adding more self-transcendent motives.

This study was a contribution in part because it counteracts potential stereotypes that could exist about how to motivate low-income students attending urban public schools. Many of these students said that they wanted to contribute to the world beyond themselves, not just make money. And when they did, they were more likely to demonstrate self-control and make progress toward long-term goals. This suggests that telling these students to focus on how they can make more money if they go to college may not give them the motives they need to actually make it to college graduation. Instead, perhaps cultivating motives that transcend the here and now could provide them with the personal meaning that could help them sustain the self-regulation—which they will need to continue working even when the reason for a task is unclear and when tempting alternatives abound.

More generally, the results of Study 1 raise the intriguing possibility that an intervention designed to promote a self-transcendent purpose for learning might improve adolescents’ academic performance over time. We tested this in Study 2.

**Study 2: A Longitudinal Intervention Experiment**

Study 1 was the first to show that a self-transcendent purpose for learning could predict a tendency to display greater diligence and self-regulation on academic activities as well as greater college persistence. Although encouraging support for our theory, these correlational analyses are limited in their ability to isolate causal processes. We therefore created a novel purpose for learning intervention and assessed its effects on behavior over time. This process was informed by past studies showing that even brief persuasive messages that alter students’ appraisals of
recurring events in school can improve student achievement months or years later (Aronson, Fried, & Good, 2002; Blackwell, Trzesniewski, & Dweck, 2007; Sherman, Hartson, Binning, Purdie-Vaughns, Garcia, Taborsky-Barba, Tomassetti, & Cohen, 2013; Cohen, Garcia, Purdie-Vaughns, Apfel, & Brzustoski, 2009; Hulleman & Harackiewicz, 2009; Walton & Cohen, 2011; see Yeager & Walton, 2011; Garcia & Cohen, 2012). Building on this, a one-time purpose intervention might produce a shift in students’ thinking that buffers them from a loss in self-regulation when confronted with uninteresting tasks on a daily basis (cf. Grant & Sonnentag, 2010). Specifically, we hypothesized that an intervention promoting a self-transcendent purpose for learning could improve GPA in STEM courses several months later, compared to a control group that completed a neutral exercise.

**Method**

**Participants.** Participants were 338 ninth grade students at a middle class suburban high school in the Bay Area of Northern California. Exactly half were male and half were female; 60% were Asian, 28% were White, 9% were Hispanic / Latino, and 1% were African American. The present study’s population adds to Study 1’s, which showed the importance of a purpose for learning among predominately low-income students of color attending urban public schools. In the present study, poverty and poor quality instruction were not common barriers for students; only 8% percent were eligible for free or reduced-price lunch and over 85% were considered proficient in math and science on state tests. Thus it was possible to examine whether the effects of a self-transcendent purpose could generalize beyond the type of sample employed in Study 1. There was no stopping rule for data collection in the present study because all students in the school were invited to participate.
**Procedures.** The intervention was delivered in the school’s computer lab during the school day. Teachers directed students to a website (www.perts.net) that delivered the session via a computer. All that was required of the teachers was to keep the class orderly. The materials took less than one class period (20-30 minutes) to complete.

The school has four grading periods in the year, each producing independent grades, and each lasting one fourth of the school year. In the first week of the fourth grading period of the year (in March), students completed Study 2’s web-based self-transcendent purpose intervention or a control intervention (see below). This allowed for a test of the intervention on grades in the final quarter of the year, controlling for prior grades in the third quarter.

Crucially, the intervention was delivered during an elective period, not in a math or science class. This provides a strict test of the hypothesis that students themselves could create a purposeful framework that they could apply even with no explicit associations between the intervention content and STEM course learning objectives. We made no mention to students that the purpose intervention was designed to affect their thinking or behavior—instead, it was a framed as a student survey requiring their input. No teacher at the school had access to the intervention materials (so they could not reinforce it knowingly), and they were unaware of treatment and control assignments.

**Purpose for learning intervention.** A number of insights informed our intervention design. First, in past qualitative research (Moran et al., 2013; Yeager & Bundick, 2009; Yeager et al., 2012) many high school students spontaneously named both self-oriented motives and self-transcendent motives. Students who did so showed the greatest improvements in terms of the meaning of their schoolwork (Yeager et al., 2012; for analogous research in the workplace, see Grant, 2008). Almost no adolescents (8%), however, mentioned only self-transcendent motives.
We therefore expected that teens would find it implausible to only focus on the world beyond the self, especially because high school is transparently a preparation for one’s future personal academic and professional goals. Therefore the intervention asked students to connect self-transcendent aims to self-relevant reasons for learning, rather than asking them to be completely altruistic.

Next, a premise of our approach is that it is either not possible or extremely difficult to tell a teenager what his or her purpose for learning should be. Doing this could threaten autonomy, a key concern for adolescents (Erikson, 1968; Hasebe, Nucci & Nucci, 2004; Nucci, 1996). Indeed, teens commonly express reactance in response to adults’ attempts to influence their personal goals (Brehm, 1966; Erikson, 1968), rejecting adult’s suggestions—or even endorsing their opposite—to reassert autonomy (see Lapsley & Yeager, in press). At the same time, it may be possible to lead a teenager to reflect on and construct motives in a certain direction, in a way that leads them to develop their own self-transcendent purposes for learning (see Hulleman & Harackiewicz, 2009). In past research on service learning activities with adolescents, reflecting on the personal meaning of one’s past prosocial behaviors led to changes in beliefs, attitudes, and thinking styles (Eyler, 2002; Eyler & Giles, 1999). Informed by this, our intervention did not seek to give a purpose to a student. Instead it sought to serve as an “enzyme” to catalyze students’ reflections about their own self-transcendent purposes for learning and facilitate connections to self-oriented motives.

More concretely, the intervention first primed students’ self-transcendent thoughts by asking them to write an open-ended essay response to a question about social injustices they found particularly egregious. The prompt was:

How could the world be a better place? Sometimes the world isn't fair, and so everyone
thinks it could be better in one way or another. Some people want there to be less hunger, some want less prejudice, and others want less violence or disease. Other people want lots of other changes. What are some ways that you think the world could be a better place?

Common responses dealt with issues such as war, poverty, or politics. Some examples were “Without discrimination, there would be much less violence and war in this world” or “The hunger problem can be solved if we have proper energy sources.” With those prosocial concerns in mind, students next completed a structured reading and writing exercise.

In doing so, the intervention drew on a variety of strategies designed to be maximally persuasive without threatening autonomy (Yeager & Walton, 2011; see J. Aronson et al., 2002; Walton & Cohen, 2011). The intervention conveyed the social norm that “many students like you” have a self-transcendent purpose for learning. Such descriptive norms can motivate behavior change (Cialdini, Reno & Kallegren, 1990; Goldstein, Cialdini & Griskevicius, 2008; see Cialdini, 2003), especially during adolescence (Cohen & Prinstein, 2006). To create a descriptive norm, we presented results of a survey that communicated that, in addition to common motives like making money or having freedom, most students also (sometimes secretly) are motivated to do well in school in order to gain skills that can be used for prosocial ends. Survey statistics presented to participants indicated that most students were motivated to do well in high school at least in part “to gain knowledge so that they can have a career that they personally enjoy” and “to learn so they can make a positive contribution to the world.” These statistics were also designed to counteract pluralistic ignorance about the norm that people are purely self-interested (also see Grant & Patil, 2012; Miller, 1999). As in similar social-psychological interventions (e.g., Walton & Cohen, 2011), summary statistics were accompanied
A PURPOSE FOR LEARNING

by representative quotes purportedly from upperclassmen at the school that reinforced the focal message. One such quote stated:

For me, getting an education is all about learning things that will help me do something I can feel good about, something that matters for the world. I used to do my schoolwork just to earn a better grade and look smart. I still think doing well in school is important, but for me it's definitely not just about a grade anymore. I'm growing up, and doing well in school is all about preparing myself to do something that matters, something that I care about.

Finally, building on self-perception and cognitive dissonance (Bem, 1972; Festinger, 1957), past research finds that when a person freely chooses to advocate for a message this can lead a person to internalize it (E. Aronson, 1999; J. Aronson et al., 2002). Therefore, students next wrote brief testimonials to future students about their reasons for learning. Specifically, students explained how learning in high school would help them be the kind of person they want to be or help them make the kind of impact they want on the people around them or society in general. Participants on average wrote 2-4 sentences. In this way, rather than being passive recipients of the intervention, students themselves authored it. This allowed students to make the message both personal and persuasive to the self (Yeager & Walton, 2011).

We conducted a pilot experiment to confirm that the self-transcendent purpose intervention could indeed promote personal meaning in school as expected by theory (Yeager & Bundick, 2009; also see Study 1). This pilot involved $N = 451$ high school students from 13 different high schools across the United States (extensive detail is presented in the online supplemental material). In the pilot, students were randomized to the purpose intervention or a neutral control activity (see below). Students then completed a more extended version of the
Study 1 meaningfulness of schoolwork measure—the academically-oriented BIF (Figure 1; cf. Vallacher & Wegner, 1989). As expected, in this pilot the purpose manipulation led to greater personal meaningfulness of tedious academic tasks compared to a neutral control, \( t(446) = 2.67, p = .007, d = .25 \) (Control raw \( M = 4.78, SD = 2.53 \) vs. Purpose raw \( M = 5.39, SD = 2.41 \)). This confirms that the purpose intervention can operate as expected, at least in the short term in the pilot sample.

**Control exercise.** In a control condition, participants read about and then explained how high school was different from middle school. As in the purpose condition, participants saw summary statistics, read messages purportedly from helpful upperclassman (e.g., statements discussing the differences in the number of teachers or difficulty of time management), and wrote essays about how their lives were different now compared to when they were in middle school. Thus the control exercise was age-appropriate, social, and engaging, but was devoid of the focus on motives for learning. It primarily rules out the alternative explanation that any positive and friendly message about school from older students could create a sense of connection with others and facilitate prosocial motivation.

**Measures.**

**STEM Grade point average (GPA).** The primary dependent variable was grades in STEM courses (math and science) for the fourth grading period of the year. As is common, we scored grades from individual courses on a four-point GPA scale (i.e., A = 4, A- = 3.67, B+ = 3.33, etc.) and then averaged them. We did the same for the pre-intervention grading periods. Math courses were Algebra 1, Algebra 2, or Geometry (depending on where guidance counselors placed students); all students took Biology, although some students were in more advanced Biology classes than others.
Results

**Preliminary analyses.** The two conditions did not differ in terms of word count of their written responses, $t(319) = -1.10, p = .92$, suggesting that, at least along this index, the two interventions elicited similar levels of engagement with the activity. Next, students successfully responded to the prompt. Some examples for the purpose intervention condition were:

“"I would like to get a job as some sort of genetic researcher. I would use this job to help improve the world by possibly engineering crops to produce more food, or something like that.”

or

“I believe learning in school will give me the rudimentary skills to survive in the world. Science will give me a good base for my career in environmental engineering. I want to be able to solve our energy problems.”

or

“"I think that having an education allows you to understand the world around you. It also allows me to form well-supported, well-thought opinions about the world. I will not be able to help anyone without first going to school”

**GPA analyses.** Did the purpose intervention improve overall grades in STEM-related courses (math and science)? It did, as shown in Figure 4. In an OLS regression, there was a full-sample effect of the one-time intervention on STEM-course GPA in the months following the experiment (Control covariate-adjusted $M = 2.93$, $SD = 1.03$; Purpose covariate-adjusted $M = 3.04$, $SD = .89$), $t(337) = 3.20$, $p = .001, d = .11$.\(^7\) As is standard procedure in analyses of

---

\(^7\) Cohen’s $d$ effect sizes were calculated by dividing the covariate-adjusted treatment effect by the raw, pooled standard deviation.
psychological intervention effects on GPA (Blackwell et al., 2007; Cohen et al., 2009; Walton & Cohen, 2011; Yeager, Purdie-Vaughns, Garcia, Apfel, Pebley, Master, Hessert, Williams, & Cohen, in press), this analysis was conducted controlling for prior performance (in the present case, third grading period grades; the same findings emerged controlling for all prior grading periods). Indeed, doing so reduced the standard errors associated with the condition variable, allowing for more precise estimates of treatment effects and maximization of statistical power. Additional models that added controls for race, gender, age and level of math course did not change the finding of a main effect of condition on GPA ($p = .001$). These control variables also did not moderate treatment effects (all interaction effect $p$s > .15).

Under the assumption that low-achieving math and science students might be more likely to be disinterested (see, e.g., Skinner, Kindermann, & Furrer, 2009; also see Hulleman & Harackiewicz, 2009), we tested whether the purpose for learning would have the greatest effect on students who were earning the lowest math and science grades pre-intervention. Indeed, there was a significant Purpose intervention $\times$ Pre-intervention GPA interaction, $t(338) = -2.92, p = .004$, such that lower-performing students benefitted more. To illustrate this interaction, which was tested using the continuous pre-intervention GPA variable, it is possible to examine simple effects within meaningful subgroups of lower-performers (students with a GPA $< 3.0$) and higher-performers (GPA of 3.0 or higher). A cut-point of a GPA of 3.0 was selected for this

---

8 Even without controlling for baseline performance—which reduced the standard error for the treatment effect by more than 250%—the treatment effect on final grades was marginally significant, $p = .06$.

9 While our primary focus was on STEM course GPA, the participating school also provided students’ English grades. Supplementary analyses showed that there was a full-sample effect of the purpose intervention on fourth grading period English grades of .15 grade points, $t(329) = 2.18, p = .03$, including the same covariates noted above. Perhaps this was because students found freshman year English to be boring, or perhaps this is because the intervention led to a general increase in engagement in school that spilled over to English class.
illustration because an analysis of high school transcripts and college enrollment statistics identified this as the best GPA threshold for college readiness (Roderick, Nagaoka, & Allensworth, 2006). Among lower-performers, who are typically less likely to successfully complete college on the basis of their high school GPAs, there was a significant treatment effect of 0.2 grade points, $t(119) = 2.90, p = .005, d = .21$. This is shown in Figure 4. Among higher-performers, there was a non-significant effect of 0.05 grade points, $t(207) = 1.38, p = .17, d = .06$.

Thus, the self-transcendent purpose for learning increased STEM-course grades for students overall, but especially so for low-performers who were on track for being underprepared for higher education. This result mirrors past intervention studies, which have found that lower-performing students tend to benefit most from activities that redirect their thinking about academic work in a positive way (e.g., Cohen et al., 2009; Hulleman & Harackiewicz, 2009; also see Wilson & Linville, 1982). It is of course possible that this moderation by baseline grades is a statistical issue; indeed, A, A-, and B+ students have less room to improve. At the same time, to the extent that lower grades could be caused by disinterest and disengagement (see, e.g., Skinner et al., 2009), the present moderation is consistent with the theory that the purpose intervention would confer the greatest benefits when disinterest and disengagement are greatest.

Discussion

Extending the Study 1 correlational findings, Study 2 showed that a one-time self-transcendent purpose intervention could affect overall achievement in STEM courses several months into the future. How could a brief purpose intervention increase official GPA? In the next two studies we sought to illuminate some of the behavioral processes set in motion by the self-transcendent purpose manipulation.
Study 3: Deeper Learning During Tedious Multiple-Choice Questions

Study 2 was a contribution in showing a causal effect of a one-time self-transcendent purpose intervention on accumulated behavior over time—specifically, GPA in high school STEM classes. It provides causal evidence for the kinds of achievement effects that may have produced the Study 1 correlational finding that purpose for learning predicted college persistence. However, a number of issues remain. Perhaps most importantly, Study 2 did not document which short-term behaviors were affected by the intervention and that subsequently added up to the long-term treatment effect. For instance, we do not know if a self-transcendent purpose increased overall grades by making students more likely to truly learn from their academic experiences, as opposed to moving as quickly as possible through their academic work without trying to retain the information for future use (see Jang, 2008).

Study 3 was a naturalistic field experiment conducted among undergraduates preparing for one of their final exams in their psychology course. A few days before the exam, the instructor emailed students a survey link that randomized them to a purpose intervention or a control exercise. The survey then directed students to complete a tedious (>100-question) web-based test review. Our hypothesis was that the self-transcendent purpose intervention would increase students’ attempts to seriously review the material, operationalized as the average amount of time spent on each question. Notably, the materials were presented as an actual extra-credit exercise, not as a study, in order to more closely re-create the real-world choices students might have been making in Study 2.

Method

Participants. A total of 89 second- through fifth-year students in an undergraduate psychology course received an email inviting them to access a test review and receive extra
credit. A total of 71 (80%) completed the intervention materials and provided any data on dependent measures. Of these, 78% were women. There was no stopping rule because all students in the class were invited. No data were excluded.

Note that in this study (and Study 4), participants are college students, not high school students. In part this is because of our interest in understanding the processes that lead to the attainment of long-term educational goals such as college graduation (e.g., Study 1). This sample was also convenient. This difference in sample provides the benefit of possibly generalizing the prior results. It would be informative if a self-transcendent purpose for learning produced analogous effects among high school freshmen (Study 2), high school seniors (Study 1), and college students (Studies 3 and 4).

Procedure. Near the end of the term, students completed the online purpose intervention and exam review activity. During the review activity, the survey software tracked students’ behavior (e.g., time spent on each practice problem) and this constituted the primary dependent measure.

More specifically, two days before an exam, students were sent the following email from their professor:

Hello class. I'm currently working on an online activity to help the students in my class do better. This online activity involves two things. First, it helps you think about how our psychology class fits into the context of your lives. Second, I've created an online activity to help you study the course material and prepare for your next exam, which involves showing you several sample multiple-choice questions that are similar to the kinds of questions that you will be tested on during EXAM 3. Since this online tool is still a work in progress, I’m offering you 2 points extra credit (to be applied to your
lowest exam score) if you decide to go through it and help refine it. … [It] will take as long as you'd like—you can answer as many or as few questions as you want.

**Purpose and control exercises.** The self-transcendent purpose materials were highly similar to those used in Study 2. They were edited slightly to refer to reasons for learning psychology, so that the materials could conceivably be seen as related to the psychology course. The normative quotes were also framed as coming from former students in the course, as opposed to upperclassmen in general. The control exercise was highly similar to the Study 2 control group, only it discussed how learning in college is different from learning in high school. Both of these changes were made because the experiment was conducted as “institutional research,” which means that from the students’ perspectives it was not a research study but rather an attempt to help them do well on their upcoming test. And in fact the review boosted grades, dramatically so for the lowest performers (see online supplement). This ethics arrangement also had implications for random assignment. Because the research team already possessed evidence that the intervention could benefit students (e.g., Study 2) and because there were real-world grades at stake for students, for ethical reasons 75% of students received the purpose intervention and 25% received the control. Furthermore, to preserve the view that this was a normal class activity as opposed to a research study, no self-report attitudes or other psychological measures were assessed. Only students’ post-manipulation behavior on the review materials were measured.

**Measures.** As a dependent measure, we created a situation that was tedious: reviewing for a test by answering over one hundred multiple-choice question. We then measured behavior that could signify an intention to truly learn from it: time spent on each review question. All questions were taken from a psychology test bank. On average, students answered 90 questions
and spent 40 minutes doing so. Review questions were programmed so that students could not proceed to the next question until they answered it correctly, and task instructions clearly stated that spending more time on each question—rather than just guessing randomly and moving on—signaled a desire for deeper learning. The instructions were:

**IMPORTANT: HOW TO ACTUALLY LEARN FROM THESE QUESTIONS**

New cognitive psychology research shows that simply guessing on multiple-choice questions does not promote deep learning on the activity, because it doesn't force you to retrieve the information…. So, if you want to deeply learn from this activity, it is best to look through your notes and the textbook and try to recall the information while answering the questions, as if you were really taking an important exam.

Students were also given web links to actual published empirical articles supporting these conclusions. Thus, we assumed that in general the longer students thought about each question before trying to answer it, and the longer they spent clarifying their understanding before moving on, the more they were choosing to “learn deeply” from the activity. We conducted a number of additional analyses to confirm this theoretical interpretation of the data, and they are reported in the online supplement.

The survey software recorded the number of milliseconds that each question was displayed before students ultimately submitted a correct answer. These values were summed and then divided by the number of questions attempted, to produce an average time per question per person. Treatment versus control students did not differ in terms of the number of questions students completed, $p = .38$, but the effect was in the direction of treated students completing more problems (see online). As is common in analyses of time, this measure showed significant skew and kurtosis (joint test $p < .00001$). We therefore conducted a “ladder of powers” analysis
(Tukey, 1977) to identify the transformation that best reduced deviation from normality (it was one divided by the square root of the number of seconds). The ladder analysis and subsequent transformation were done blind to the effect of the transformations on the significance of the intervention effect. The transformed measure had no significant skew or kurtosis, joint test \( p = .90 \). Time was ultimately coded so that higher numbers corresponded to more time on average on each page, and then z-scored to have a mean of zero and a standard deviation of 1. All analyses are from regressions that control for prior test performance, which significantly predicted time per page and reduced standard errors associated with treatment effects.

**Results**

Results showed that a self-transcendent purpose for learning increased the tendency to attempt to deeply learn from tedious academic tasks. Students who completed the self-transcendent purpose intervention spent more time working on each review question (Z-scored time per question: Control \( M = -0.43, SD = 1.11 \); Purpose \( M = 0.13, SD = 0.93 \)), \( t(69) = 2.11, p = .038, d = .56 \). In the untransformed data, this corresponded to spending roughly twice as much time on each question (Control \( M = 25 \) seconds per question vs. Treatment \( M = 49 \) seconds per question).\(^{10}\)

**Discussion**

Study 3 investigated one of the short-term behaviors that might have led to the long-term effects of a purpose in Study 2: deeper learning on a tedious exam review. Students spent twice as long on their review questions when they had just written about how truly understanding the

\(^{10}\) It was also possible to explore treatment effects on actual scores on the final exam administered a few days after the study. Exploratory analyses found that the large majority of students showed greater improvement in test scores in the purpose condition as compared to the control. Analyses are presented in the online supplement.
subject area could allow them to contribute to the world beyond the self, compared to controls. Importantly, this was done in a naturalistic setting—that is, looking at real world student behavior on an authentic examination review, when students were unaware that they were in a random-assignment experiment. Perhaps the purpose intervention increased grades over time in Study 2 because it led students to complete their academic work in a qualitatively distinct fashion—one that privileged learning and retention over “getting through it.”

**Study 4: Working Hard in the Face of Temptations**

The findings from Study 3 suggest one way in which a one-time self-transcendent purpose intervention might have increased overall grades in STEM courses in Study 2: deeper learning during review activities. However we have not shown that the purpose manipulation altered students’ abilities to regulate their competing desires. That is, we have not shown effects in situations that clearly require self-regulation. To begin to answer this, a more precise behavioral test is required—one that pits the desire to meet one’s learning goals against the desire to give up and engage in a tempting alternative.

Therefore Study 4 examined behavior on the “diligence task” described in Study 1 (also see Figure 2). This task simulates a common experience for students: having to complete problem sets for math and science classes while being tempted to consume entertaining media on the Internet. Thus, the present study allowed for a face-valid test of our hypothesis that a self-transcendent purpose for learning could lead students to continue to solve math problems and eschew tempting alternatives even as boredom is increasing.

Second, it would be helpful to know if a self-transcendent purpose could benefit all learners, but especially when a task is most uninteresting. Therefore, instead of examining between-person differences that might moderate treatment effects, as in Study 2, Study 4 focused
on within-person differences. That is, Study 4 examined whether the purpose manipulation would lead to more math problems solved on the later trials of the diligence task, when boredom is greatest.

Study 4 was primarily designed to address these two research questions. However a third objective was to test whether simply emphasizing the self-oriented benefits of learning in school would be sufficient for promoting academic self-regulation. Recall that Studies 2 and 3 compared the purpose manipulation to a neutral control exercise, something that has often been done in many past social-psychological interventions that have affected long-term educational outcomes (e.g., Hulleman & Harackiewicz, 2009; Walton & Cohen, 2011). Yet it is unknown whether an analogous self-oriented manipulation would show the same benefits as the purpose manipulation. While Study 1 is helpful in showing the unique correlational effect of a self-transcendent purpose, an analogous experimental study has not been conducted. To address this, in the second of the two samples included in the present study we added a self-oriented condition, making it a three-cell design. We hypothesized that the self-oriented condition would not be sufficient to lead to higher numbers of math problems solved when boredom was greatest, as compared to controls. We did not have a strong prediction about the comparison between the self-oriented condition and the purpose condition, however, because the former was intentionally designed to share much of the same content, and because past research has found these two groups do not differ significantly (Yeager et al., 2012; also recall the inconsistent Wald test results in Study 1).

Method

Participants. Participants (total $N = 429$) were two samples of students taking introductory psychology at the University of Texas at Austin in consecutive semesters. They
participated in exchange for partial course credit. Forty-eight percent were male and 52% were female. Race and ethnicity information was not collected from these students; however, the freshmen cohort at the university (which historically closely mirrors introductory psychology) is 57% White, 18% Asian, 17% Hispanic / Latino, and 5% African American. Students were predominately first or second year students: 37% were 18 years old, 36% were 19 years old, and 15% were 20 years old. Data were collected during daytime hours in the last few days of the semester, a time when self-regulation might have been precarious due to final exams.

Sample 1 had no stopping rule. We sought to collect as much data as possible (final \( n = 117 \)) before the end of the term, and data were not analyzed until after the term was over. Sample 2 was collected the following semester and so it was possible to conduct a power analysis based on the results of Sample 1 before collecting data. This led to a target sample size of 300 for Sample 2, because a power analysis revealed that roughly 95 participants per cell would be required to have 80% power to detect an effect of \( d = .41 \) between any two conditions (the effect size estimate for the purpose intervention from Sample 1). Ultimately Sample 2 involved usable data from a maximum of \( n = 312 \) students (data collection was stopped at the end of the first day on which more than 300 complete responses had been collected). Some students did not provide data for some measures, and so degrees of freedom varied across analyses. No data were excluded except for those mentioned here or in the online supplement.

**Procedures.** The intervention procedures were nearly identical to those used in Study 3. Immediately after completing the intervention materials, participants completed the diligence task as described in Study 1.

**Purpose and control exercises.** These were nearly identical to those used in Study 2.
**Self-oriented control exercise.** Sample 2 had a three-cell design that added a self-oriented (and intrinsic) condition to the control and self-transcendent purpose conditions. The self-oriented manipulation was similar to the purpose manipulation in nearly every way except for the elimination of self-transcendent oriented prompts in the stimuli. It was future-oriented, goal-directed, and highly focused on learning and on developing skills—all things expected by theory to promote a commitment to learning (e.g., Lepper et al., 2008; Ryan & Deci, 2000; Vansteenkiste et al., 2006). This is a highly conservative test in that the manipulations shared much of the same content—approximately 90% of the text was the same. Also recall that Study 1 indicated that self-transcendent and self-oriented motives were strongly correlated, \( r = .66 \). The present self-oriented control group was designed to rule out the alternative explanation that any manipulation involving reading and writing about intrinsic personal motives for learning would be sufficient to lead to greater self-regulation on an uninteresting task.

In the self-oriented exercise, an initial essay question asked about changes in the world. This held time-perspective and counterfactual thinking constant, both shown to affect level of construal, which could promote self-regulation (Trope & Liberman, 2010; 2011). However this prompt asked how the world might be changed to benefit the self, rather than to address an injustice in the world:

How could the world be better for you? Sometimes the world isn't what you want it to be, and so everyone thinks it could be better for them in one way or another. Some people want more fun, some want it to be less stressful, and others want to be more interested in what they’re doing. Other people want lots of other changes. What are some ways that you think the world could be better for you?
All but one of the summary statistics and all but one of the representative quotes were identical across conditions. For the one quote that was not the same, we removed self-transcendent information without sacrificing a focus on building skills, so that it read:

"For me, getting an education is all about learning things that will help me do something I can be good at—something that I can be the best at. I used to do my homework just to earn a better grade and look smart. I still think doing well in school is important, but for me it's definitely not just about a grade anymore. I'm growing up, and doing well in school is all about preparing myself to do a job that I can be good at. That seems really rewarding to me—knowing that at the end of the day you completed an important job, and you did an awesome job at it" (differences from the quotation in Study 2 shown in italics).

Next, participants were asked to share their own testimonials. The prompt closely mirrored the purpose condition and strongly emphasized the acquisition of skills (rather than the accumulation of extrinsic benefits). It asked “Why is learning important to your goals”, and “How will learning in school help you be the kind of person you want to be and help you have a career in life that you enjoy or are interested in?” Note that this prompt promotes a mastery orientation, which might be expected, on its own, to benefit students. Yet it omits explicit mention of the potential to use that mastery to benefit others, allowing for a test of our theory regarding the benefits of adding self-transcendent motives to self-oriented ones.

**Measures.** Participants completed the same behavioral measure of academic self-regulation (i.e., the diligence task) that was used in Study 1 (see Figure 2). As in Study 1, we
analyzed the total number of correct math responses.\textsuperscript{11} Performance on each of the two blocks was analyzed separately to allow for a test of whether self-regulatory benefits would be greatest when boredom had increased. To verify the extent to which the task was boring for participants in all conditions, at the end we asked participants whether the task was in fact boring, using the same item described in Study 1.

**Results**

**Analytic plan.** The primary theoretical interest was in whether the purpose for learning condition differed from the control condition in terms of behavior on the diligence task. Because, as will be shown, this focal comparison was significant independently within Samples 1 and 2, we primarily analyze a stacked dataset and in statistical models we include a dummy variable for sample (and of course the self-oriented condition data are excluded in those analyses).

A secondary question was whether the self-oriented manipulation produced the same or a different pattern of results as the purpose for learning manipulation. Therefore we next conducted analyses of the self-oriented manipulation using only data from Sample 2. We hypothesized that the self-oriented condition would not differ from controls. We did not have strong hypotheses about differences from the purpose condition, given the overlap between the two manipulations and the strong endorsement of learning goals in the self-oriented condition.

**Preliminary analyses.** The experimental manipulations again appeared to elicit similar levels of thinking and writing about their respective topics; there were no differences across conditions in terms of the word count on the open-ended essay prompts, Sample 1: $t(116) = .50$, $p = .62$.

\textsuperscript{11}As in Study 1, we treated people who stopped the task altogether after the first block as a “0”, as in Study 1, to avoid dropping data. The statistical significance levels of the focal analyses (Block 2 math problems successfully answered) were no different when omitting participants who did not begin Block 2.
n.s., Sample 2: \( F(2, 282) = .13, n.s. \) Next, the diligence task was experienced as truly boring. Fully 73% of participants said they were “Extremely,” “Very” or “Somewhat” bored when working on the math problems, while only 4% said they were “not bored at all.” Ratings of boredom did not differ by condition: Sample 1 \( t(116) = .47, n.s. \), Sample 2: \( F(2, 282) = 1.27, n.s. \). Thus, this study was a test of whether participants would display greater self-regulation on a task that was experienced as equally boring across conditions.

**Primary analyses.** Did the self-transcendent purpose manipulation affect the number of math problems correctly solved? On the first block in the stacked dataset, the purpose manipulation had no effect compared to the control, \( t(310) = 0.18, p = .86 \) (or in either sample, Sample 1: \( t(116) = .19, p = .85 \); Sample 2: \( F(2, 283) = .57, p = .56 \)). However recall from the methods of Study 1 that the second block in the diligence task is experienced as much more tedious and aversive compared to the first block (and significantly so). Therefore differences were predicted to emerge precisely when participants became most bored, in Block 2.

This is what the data showed, as depicted in Figure 5. Specifically, for participants in the control condition, the number of math problems solved dropped precipitously from the first to the second block. Control participants completed 44% fewer problems in Block 2 compared to Block 1 (Control Block 1 raw \( M = 66.47, SD = 46.29 \); Control Block 2 raw \( M = 37.12, SD = 45.10 \)), a significant difference, paired \( t(164) = 7.51, p < .001, d = .65 \). However, for participants who completed the purpose manipulation, the drop in math problems solved from the first to the second block was mitigated. Purpose condition participants completed only 26% fewer problems in Block 2 (Purpose Block 1 \( M = 68.62, SD = 45.11 \); Purpose Block 2 \( M = 50.56, SD = 49.00 \)), still a significant difference, paired \( t(165) = 4.21, p < .001, d = .38 \). Importantly, an OLS regression analysis comparing difference scores (Block 2 problems solved minus Block 1
problems solved, by condition) showed that the decline experienced by the purpose condition was significantly smaller than that experienced by participants in the control condition, $b = 12.45, t(309) = 2.10, p = .03, d = .28$. Thus, by the second block, there was a significant effect of the purpose manipulation compared to the control, $t(309) = 2.81, p = .005, d = .32$, such that purpose condition participants completed 36% more boring math problems compared to controls in the second block. This condition difference in Block 2 was significant independently within Sample 1, $t(115) = 2.14, p = .03, d = .40$, and Sample 2, $t(192) = 2.13, p = .03, d = .31$, and did not differ across samples, interaction $t(308) = 0.11, p = .90$. Hence, it was a reproducible finding (see Figure 5).

**Comparison to the self-oriented control group.** By contrast, the highly-similar self-oriented control group—emphasizing intrinsic motives for learning—did not appear to improve self-regulation on the boring math task compared to controls. Recall that these analyses could only be conducted with data from Sample 2, which is the sample that involved the three-cell experiment. The self-oriented condition did not differ from the control in terms of number of math problems solved, either in Block 1, $t(287) = .90, p = .39, d = .11$, or Block 2, $t(287) = .92, p = .38, d = .11$, although comparisons were in the direction of more math problems solved for the self-oriented group versus the control. Note that this non-significant difference is not likely due to limited statistical power; the purpose condition showed a significant difference from control on Block 2 in Sample 2 (see Figure 5). The self-oriented condition did not differ from the purpose condition in either block, Block 1, $t(285) = 1.37, p = .17, d = .16$, Block 2, $t(285) =-.99, p = .32, d = .11$.

Also informative is an analysis of changes across blocks. Participants in the self-oriented condition showed a decline in the number of math problems solved that mirrored the control
condition, as shown in Figure 5. Participants in the self-oriented manipulation condition solved 32% fewer problems in Block 2 than in Block 1 (Self-oriented Block 1 $M = 82.43$, $SD = 73.52$; Block 2 $M = 55.63$, $SD = 45.65$), $t(86) = 6.00$, $p < .001$, $d = .45$. An analysis of difference scores found that this change across blocks did not differ from the same changes seen in the control condition, $t(286) = 0.35$, $p = .73$. However the change score did differ significantly from the changes seen in the purpose condition, $t(286) = -2.17$, $p = .03$, $d = .26$, showing that the purpose manipulation was significantly better at warding off a decline in math problems solved across blocks compared to the highly similar self-oriented manipulation.

Inspecting Figure 5, it is interesting that students in the self-oriented manipulation condition showed an initial, non-significant boost in Block 1 problems solved compared to controls. This may have been contributing to the significant comparison between the purpose and self-oriented conditions in terms of difference scores across blocks. It is possible that the self-oriented manipulation led individuals to try harder initially, on Block 1, but this effort sapped their self-regulatory ability on the subsequent trial, Block 2. This will be important to investigate in future research. Regardless, simply reading and writing about intrinsic self-relevant motives for learning did not lead to significant differences from controls when the task became most boring. By contrast, a highly similar activity that added self-transcendent motives was effective at sustaining self-regulation.

**Discussion**

Study 4 extended the evidence about the effects of a self-transcendent purpose on academic self-regulation. We put learners in a situation in which they were asked to complete a tedious, low-level task that had only a tenuous relationship to future work goals, and they were told they could quit at any time and entertain themselves online. In many regards this is the
modern dilemma: with ubiquitous entertainment at our fingertips, learners must exercise self-discipline even when they do not know whether they themselves or someone else will benefit from their hard work in the long term. We showed that learners could be helped in such situations when they reflected on how their future role in society might contribute in some ways to the world beyond the self. These individuals were better able to maintain their level of persistence and overcome temptation even when boredom was increased.

**General Discussion**

Many repetitive, foundational, skill-building math and science tasks are experienced as tedious or boring (Raytheon Company, 2012; Stigler & Hiebert, 1999). Our research found that in such instances it can be helpful to focus on creating personal *meaning* by promoting a prosocial, self-transcendent *purpose* for learning (see Brophy, 2008).

In correlational, experimental, and longitudinal studies involving roughly 2,000 high school and college students, a purpose for learning predicted or caused more effective academic self-regulation in the immediate term and over time. A self-transcendent purpose was correlated with more diligence in the face of tempting alternatives and also greater college persistence rates among low-income, urban minority students (Study 1). A brief experimental intervention to promote a self-transcendent purpose increased overall STEM-course grades several months later (Study 2). Studies 3 and 4 clarified the nearer-term effects of this manipulation. A self-transcendent purpose doubled the amount of time students spent on tedious exam review questions (Study 3) and increased by 35% the number of boring math problems students solved compared to controls, even when they had the option to consume entertaining Internet media at any time (Study 4). Adolescents with more of a self-transcendent purpose for learning also literally saw learning tasks differently. They were more likely to say that pictures and
descriptions of quotidian academic tasks were linked to important and personally-meaningful academic goals (Study 1; also see the pilot randomized experiment reported in the online supplement). All told, it seems that when adolescents had a prosocial, self-transcendent “why” for learning they were able to bear even a tedious and unpleasant “how” (cf. Frankl, 1963).

Previous research has shown that having a prosocial, self-transcendent motive for engaging in a behavior can lead to greater persistence on repetitive and uninteresting tasks at work (see Grant, 2007, 2013). The present research extended this by examining situations in which a person was working on skill-building tasks that have no immediate payoff for others—such as doing single-digit subtraction or completing tedious multiple-choice questions. We found that a self-transcendent purpose for learning could alter a person’s self-regulation on tasks that are tedious but also prepare one to make a contribution in the future.

This type of result might well generalize to non-school settings. Do armed forces cadets engage in more vigorous physical exercise when they see themselves as preparing to protect civilians from harm versus protecting themselves from harm? Do computer hackers spend more hours learning syntax when they anticipate using it to resist an oppressive government versus stealing money or content for personal consumption? We believe the findings here might offer a perspective on the causes of persistence on foundational skill-development tasks in a number of settings in which one’s current behaviors might be viewed as preparatory for a personally-important yet self-transcendent contribution.

**Contribution to the Study of Purpose and Relevance**

The present research is also an advance because it documents the development of a new research tool to examine the causal impact of a self-transcendent purpose for learning. Unlike research that has developed psychological interventions to undo the belief that academic struggle
might mean you are “dumb” (Aronson et al., 2002; Blackwell et al., 2007; Wilson & Linville, 1982), or that you might not belong or be valued in a setting (Cohen et al., 2009; Cohen & Sherman, 2014; Walton & Cohen, 2011), research on youth purpose has to date been limited mostly to correlational survey analyses or qualitative interviews, preventing strong causal inferences (Bronk, 2012; Burrow & Hill, 2011; Yeager & Bundick, 2009; see Hill, Burrow, & Sumner, in press). The intervention developed here has the advantage of web-based scalability and replicable effects in a different populations using different outcomes. It will hopefully spawn future experimental investigations on the effect of a purpose for learning.

Another innovation of this research stems from the fact that the self-transcendent purpose affected consequential educational behaviors. Behavioral economic strategies such as paying students for completing their homework have been applied broadly and found to have no consistent positive effects on achievement (Fryer, 2011). Yet a free, roughly 20-minute, web-based intervention led students to choose to persist on unpleasant academic tasks and also earn higher grades. This is a testament to the power of precise psychological theory to lead to behavior change in situations where more traditional economic efforts fail (also see Ross & Nisbett, 1991).

**Understanding Long-Term Effects**

Social psychology has a long history of documenting counter-intuitive but reproducible effects of brief interventions that affect health, stress, or achievement months or years later, even though the mechanisms for these effects have remained obscure (e.g., Cohen & Sherman, 2014; Wilson & Linville, 1982; see Pennebaker, 2004). In these past studies and in the present research, it is often easier to understand why a manipulation would affect immediate outcomes than it is to understand why the intervention would “stick” over time, resulting in effects on
overall GPA (Cohen & Sherman, 2014; Yeager & Walton, 2011). High school students undoubtedly receive many messages from valued adults entreating them to pay greater attention to their schoolwork. Why would the brief message delivered over the Internet in Study 2 stand out?

Extant theory and some of the present data speak to this issue, but more research is needed. Specifically, theory has pointed to the fact that school is an environment in which recursive processes abound. Later knowledge builds on prior knowledge, later interactions with peers or teachers depend on relationships and reputations built in prior interactions, and later self-views and goals depend on prior thoughts and experiences (Cohen et al., 2009; Cohen & Sherman, 2014; Yeager & Walton, 2011). When a social-psychological intervention redirects a key motive for doing well in school, then it is possible for a “virtuous cycle” to gain momentum and affect diverse outcomes. A social psychological intervention might add up to accumulated effects via small adjustments in the probabilities of exerting self-control or deeply learning during tedious tasks (Abelson, 1985; also see Cohen & Sherman, 2014; Garcia & Cohen, 2012; Walton, in press).

It is crucial to underscore the fact that the self-transcendent purpose intervention is not a “magic bullet” for underachievement. Rather, it is context-dependent solution to a particular psychological barrier (Cohen & Sherman, 2014; Yeager & Walton, 2011)—in this case, the sense that tedious academic tasks are meaningless and have no connection to one’s purpose in life. In settings or among individuals where this belief is not prominent—or in settings that are not quite as recursive—then the type of intervention tested here would not be predicted to have a lasting effect. We think of the present results as an existence proof, not a guarantee that identical effects of the same sizes will occur across all settings. More generally, research designed to
understand the mediating mechanisms of brief interventions and likely boundary conditions for them is a high priority in social psychology (Cohen & Sherman, 2014; Garcia & Cohen, 2012; Walton, in press; Yeager & Walton, 2011; also see Wilson, 2011).

**Limitations and Future Directions**

One limitation of our research is that we did not investigate participants’ strategies for self-regulation. Did participants with more of a self-transcendent purpose engage in mental actions to make uninteresting tasks more appealing or were they simply better at suppressing the urge to quit and engage in the tempting alternative? Past research suggests that both are possible (e.g., Fishbach & Shah, 2006; Fishbach et al., 2010). For instance, Sansone, Weir, Harpster, and Morgan (1992) showed that when participants were asked to complete an uninteresting task and were given a rationale for why it might be personally important, participants implemented ways to make it feel subjectively more interesting. They randomly varied their method of completing the task (also see Sansone, Wiebe, & Morgan, 1999). Meanwhile, Mischel, Ebbesen, and Zeiss (1972) found that self-regulation on a delay of gratification task was facilitated through cognitive strategies to mentally transform the tempting alternative into something that felt less appealing. Unpacking which of these alternative strategies emerge from the self-transcendent purpose for learning could shed light on the underlying psychological processes in the present research.

A crucial caveat is that our research does not definitively show that intrinsic interest-driven motives are unimportant for self-regulation. Instead, what we showed was that with the same statistical power the self-transcendent purpose manipulation was more reliably different from the control than the self-oriented manipulation (Study 4; also see the Study 2 pilot reported in the online supplement), and that self-transcendent motives were sometimes but not always stronger predictors than self-oriented ones in a multiple regression (Study 1). The finding that the
intrinsic-interest-driven motives were “in the middle” mirrors past longitudinal research (Yeager et al., 2012), and has some intuitive appeal. If learners are seeking tasks that interest them or have some other intrinsic benefit to them, then they may show a general boost in motivation on school-related tasks. However, those only seeking benefits for the self may not persist on aversively tedious, low-level learning tasks in the face of alternatives that more readily satisfy their desire for interesting activities.

The present research has focused on the role of a purpose for learning in skill-building activities. However when expert performance is of interest, then the belief that others are counting on you to perform well may not be beneficial. Such worries may interfere with working memory and increase the chance that a person will “choke” due to heightened anxiety (Beilock, 2011). Indeed, experimental procedures designed to induce anxiety and undermine performance sometimes explicitly involve telling participants that others’ outcomes will be negatively affected if they fail (e.g., see Beilock, Kulp, Holt, & Carr, 2004). Thus, we believe that an important avenue for future research will be to illuminate whether a self-transcendent purpose is as effective in performance contexts as it appears to be in learning contexts.

**Conclusion**

In a recent nationally-representative survey, 69% of American K-12 teachers reported that students’ lack of interest in learning was a problem in their classrooms. In fact, this was the classroom problem most frequently cited by teachers (Bridgeland, Bruce, & Hariharan, 2013). Of course, sometimes low motivation can be addressed by simply making coursework more interesting. Yet not all assignments can be made interesting at all times. If a teacher connects the day’s lesson to the idiosyncratic interest of one student (for instance, emphasizing the relevance of math for understanding baseball) it may disengage another student (for instance, a
student who does not like baseball). Even when relevant connections can be made for large groups of students, it can be difficult, logistically, to do this for all tasks every day.

In such instances, as we have noted, a self-transcendent purpose might effectively lead to self-regulation. Strikingly, however, there is little or no focus on promoting these self-transcendent aims in expert guides for educational practitioners (e.g., National Research Council, 2000, 2004; Pintrich & Schunk, 2002; Mitchell, Shkolnik, Song, Uekawa, Murphy, Garet, & Means, 2005). We hope the present experimental interventions, combined with past experimental research (e.g., Grant, 2007, 2013; Olivola & Shafir, 2013), can begin to encourage a shift in thinking. Of course, encouraging a self-transcendent motive is not a replacement for other motivational strategies, especially not self-oriented, interest-based ones. But the data presented here demonstrate that a self-transcendent motive can in some cases be an important addition to interest-based approaches.

A PURPOSE FOR LEARNING

Figure 1. Sample item assessing the meaningfulness of schoolwork

Doing your math homework

Choose the description that *more naturally comes to your mind* when you see the picture.

- Typing numbers into a calculator and writing formulas.
- Building your problem-solving skills.
Figure 2. The “diligence task:” A behavioral measure of academic self-regulation.
Figure 3. A self-transcendent purpose for learning predicts long-term persistence toward an academic goal (enrollment at a four-year college 6-10 months post-assessment) in Study 1. Note: Predicted values that adjusted for cognitive ability, gender, racial minority status, and high school grade point average. All participants are high school graduates who stated that their goal was to graduate from college.
Figure 4. A self-transcendent purpose for learning intervention raises grades in math and science for all students but especially for poor performers in Study 2 (students with a GPA below 3.0 in the pre-intervention quarter). Error bars: 1 standard error.
Figure 5. A self-transcendent purpose for learning intervention sustains self-regulation on the “diligence task” in Study 4.

Error bars: 1 standard error.
Online Supplemental Material
Overview

This online supplement has the following information:

- Additional analyses and information about each of the five studies from the manuscript.
- Detail on the pilot study for the Study 2 intervention, assessing immediate effects on the meaningfulness of schoolwork.
- Additional text from the self-transcendent purpose intervention.
- The full personal meaningfulness of schoolwork measure.

Study 1

Validity evidence for the diligence task. A large-scale validation study with two diverse samples of twelfth grade students from the Northeast US (total $N = 826$; Galla et al., 2014) indicated that the task demonstrated convergent validity with composite scores of self-control, grit, and conscientiousness (Pearson $r$ .14 to .24 for Study 1; $r$ .16 to .20 for Study 2, $p < .01$), discriminant validity with unrelated constructs of extraversion and neuroticism ($r_s = -.02$ to .02 for Study 1; $r_s = -.07$ to .05 for Study 2; $p > .05$), and incremental predictive validity by predicting senior-year GPA ($\beta = .22$ in Study 1 and $\beta = .09$ in Study 2) and standardized math scores ($\beta = .12$ in Study 1 and $\beta = .16$ in Study 2) after controlling for demographics (socioeconomic status, gender, ethnicity), IQ (fluid and crystallized intelligence), and baseline math fluency.

Validity of brief cognitive measures. In a sub-sample of $n = 271$ students in the present study at four schools, we had the opportunity to administer the full Kaufman Brief Intelligence Test (Kaufman, 1990) and the symmetry span task (Kane, Hambrick, Tuholski, Wilhelm, Payne, & Engle, 2004). These were significantly correlated with the present brief Raven’s measure, $rs = .40$ and .32, $p < .001$, respectively (and these correlations are not substantially different from the same correlations with the full Raven’s measure; in a different pilot conducted by members of our research team with 100 participants from the Amazon Turk website [Buhrmester, Kwang, & Gosling, 2011], these correlations were $r = .46$ and .26, $p < .01$, respectively).

Accounting for zero inflation in the diligence task. The behavioral measure—number of boring math problems solved correctly—was zero-inflated because many students only consumed tempting media, and some experts (J. Cohen, P. Cohen, West, & Aiken, 2003) have noted that in some cases OLS estimates can be distorted when predicting such measures. Therefore we repeated our analyses conducting a negative binomial regression. The same results emerged: a purpose for learning was a significant ($p < .05$) predictor of solving more problems, controlling for other motives for learning.

Study 2

Effectiveness of random assignment. Random assignment was effective. Participants in the purpose condition did not differ significantly from the control condition in terms of any of the three pre-intervention grading periods, $t(331)=.47$, n.s., $t(331)=.85$, n.s., $t(331)=.90$, n.s., respectively. The conditions also did not differ in terms of gender, $\chi^2(1) = 1.18$, n.s., racial
minority status (Hispanic / Latino or African American vs. White, Asian or Other) $\chi^2(1) = .00, n.s.$, placement in advanced math courses, $\chi^2(1) = 1.99, n.s.$, or age, $t(338) = 1.19, n.s.$

**Study 3**

**Additional detail about the deeper learning procedure.** For ethical reasons we could not make students’ access to the test review contingent on their completing the intervention materials. Therefore, the survey was programmed so that students could skip any page of the intervention without writing any response; fortunately, no students did this.

In Study 3, the introductory material was clear that test review strategy that would lead to less learning would be to guess on the question right away and, if wrong, continue guessing quickly until arriving upon the correct answer by chance. If students used this strategy, time on each page would be lower on average. By contrast, a strategy that is more effective for learning and retaining the information is to think carefully about the question before trying to answer it, and, if wrong, returning to the source material or one’s notes before trying a different answer. Students might also select an answer but then change the answer once or several times before submitting the page. If students used this strategy, time on each page would be higher on average. Of course, not all students are aware that the former strategy leads to greater learning, which is why students were given this information.

**Effectiveness of random assignment.** Randomization was effective. Purpose intervention students were no different from control students in terms of their scores on the first pre-intervention exam, $t(67) = 1.42, p = .16$, the second pre-intervention exam, $t(67) = 1.49, p = .14$.

**Supplementary analyses of focal dependent variable.** There were a number of methodological decisions to make when coding and analyzing the primary dependent variable—deeper learning behavior on the tedious test review. Here we examine what impact these decisions had on our primary conclusions.

First, we were aware of the possibility that students could take longer on each question because they were distracted or not paying attention; after all, students completed the tasks in naturalistic settings, presumably wherever they typically study. If this were true, then these distracted students would also be expected to need more guesses before identifying the correct answer to a question. There is no reason to expect that this would vary across conditions but it might have added error variance. Next, it was possible that higher-performing students should be able to answer more questions on their first guess, without much thought, and so their time per page might be lower on average, but only because they moved quickly through easier questions before spending more time on harder questions. To address these possibilities, the survey software also tracked the number of times participants selected a different response option on each page. Thus analyses could control for the average number of guesses per page so as to reduce variance in average time per page due to distraction or overall background knowledge of psychology. The number of guesses on each question did not differ by condition ($p > .3$). When conducting analyses controlling for average number of clicks on each page there was still a significant treatment effect, $b = .66, t(69) = 2.33, p = .023$. 
Next, we re-conducted analyses when (a) treating as missing data any time measurement for a given page that was greater than 5 minutes, in order to reduce the possibility that our results were due to students leaving the task (e.g., to eat lunch), and (b) analyzing total number of seconds spent on the test review, as opposed to average time on each screen/question. These analyses supported the same overall conclusions (the main effects and interactions reported in the text were significant at $p < .05$ or marginally significant at $p < .06$).

**Effects on final exam scores.** Finally, recall that Study 3 was conducted in the context of a review for an exam. Although our primary dependent variable was deeper-learning behavior on this review exercise, it was also possible to explore whether the purpose intervention affected exam performance 1-2 days after the review activity. In an OLS regression predicting exam scores there was a positive but non-significant treatment effect in the full sample, $b = 2.21$ points out of 100, $t(69) = 1.02, p = .31$. This is the equivalent of going from an 85 to an 87 on the final exam.

Finding a significant treatment effect on an exam for all students, however, is a tall order for a brief intervention. In contrast to Study 2, which allowed for the possibility of many student actions over several months to add up to an overall effect on grades, Study 3 involved only one assignment—a test review that covered many weeks’ worth of content. Students who spent many weeks not paying in attention or not coming to class—for instance, failing students—might have been seeing the content for the first time when they began the test review. If these students skipped the class meetings they would presumably not have any notes to review when completing the test activity. Among those students, perhaps all would benefit from the test review because they would be getting answers to questions they had never seen (the survey was programmed to not let them move on until they got the right answer). Hence the marginal benefit of the purpose intervention (about 30 seconds more per page) might be overshadowed by the overall effect of being given the answer to questions students had neglected throughout the semester. Consistent with this hypothesis, all low-performing students (i.e., students with a D average or below) improved their grade on the final exam, presumably as a result of the test review (Previous exam average: 67%; Final exam average: 78%, $t(18) = 5.43, p < .001, d = 1.25$; values are raw and unadjusted), and this did not vary by condition, $p = .38$.

By contrast, among the majority of students who showed at least some level of engagement with the learning material prior to the purpose intervention (students with an A to C- average), and who presumably had lecture notes and other material to review, the purpose intervention led to improvements in test scores compared to controls. Within this sub-sample of 51 students, a regression predicting final exam scores and controlling for prior exam scores showed a significant effect of the purpose intervention, $b = 4.66$ points on a 100-point scale, $t(49) = 2.45, p = .018, d = .57$. More concretely, students in the control condition showed no significant improvement from the average of their previous exams to the final exam (Previous exam average: 85%; Final exam score: 85%, $t(12) = 0.05, p = .96, d = .02$). In effect, control students, who were less likely to use a “deeper learning” strategy during the test review, did not show any learning gains compared to historical performance. But they did not do worse, which is important for ethical reasons. By contrast, students in the purpose intervention condition showed significant gains on the final exam (Previous exam average: 82%; Final exam average:
88%, t(37) = 4.69, p < .001, d = .76). Having adopted a “deeper learning” strategy on the review, treated students actually learned more, it seems.

There are two important features of these findings to consider. First, the moderation by baseline performance does not mirror that presented in Study 2, which found that lower-performers benefitted most from a self-transcendent purpose. We believe this difference is more an artifact of our study design than it is support for a theoretical conclusion. That is, as shown above, all failing students benefitted dramatically from the test review. Unsurprisingly, a last-second test comprehensive review in a class they had put no effort into boosted their grade by a full ten percentage points. Among students who were at least minimally engaged in the course, however, there was a significant effect of a purpose, improving grades by nearly six percentage points in the purpose intervention and no improvement in the control. Second, it is important to acknowledge that although these moderation findings are theoretically interpretable and consistent with the overall account presented in the manuscript, they were not predicted. Therefore they should be treated cautiously until future studies replicate them. For these reasons, the findings from this exploratory analysis are reported in the online supplement and not emphasized in the main text.

**Study 4**

**Effectiveness of random assignment.** Random assignment was effective. In Sample 1, the experimental conditions did not differ in terms of age, $F(1, 116) = 0.46$, n.s., gender, $\chi^2(1) = 0.14$, n.s., or final grade in psychology, $F(1, 103) = 0.01$, n.s. (recall that the experiment was conducted at the end of the term, after all assignments except one quiz had been administered, so the manipulation could not have affected cumulative grades). In Sample 2, the experimental conditions did not differ in terms of age, $F(2, 279) = .78$, n.s., or gender, $\chi^2(2) = 0.05$, n.s. We were unable to acquire grades in the psychology course in Sample 2, but we did assess self-reported satisfaction with grades in college and found this did not differ by condition, $F(2, 282) = 1.33$, n.s.

**Notes on data exclusions and final sample construction.** Following recommendations for increasing the replicability of psychological science (Simmons, Nelson, & Simonsohn, 2011), here we outline in detail the rationale for the construction of our analytic sample and all data exclusions. We designed the study to be completed during daytime hours (7 A.M. to 10 P.M.) and not in the final hours in which studies could be completed for credit. This was done in order to prevent data collection from students who may be unable to concentrate on the study due to it being late at night or due to feeling rushed to complete the study in the final minutes in order to get credit (and perhaps participating in other online studies concurrently). For Sample 2, the survey software restricted access during nighttime hours and in the final hours before the subject pool was closed. Thus no data exclusions based on completion time were required. For Sample 1, however, that restriction was mistakenly not enforced (because the survey was not closed during the night and not ended in time on the final day of the study) and so some students participated in the late night or early morning hours or in the final two hours before the subject pool was closed ($n = 35$). We excluded these participants from analyses (and these numbers were not different by condition), in order to have comparable results across samples and to allow for a more theoretically interpretable test of our hypotheses.
Next, an important part of the task involves the opportunity to consume tempting media; however some students reported that their computers could not play the media correctly \((n = 18)\), meaning it could not have tempted them away from the boring math problems. Because these students’ data have a substantively different interpretation, they were also excluded from analyses. The effects of the purpose intervention compared to control were statistically significant when no data exclusions were carried out (i.e., \(N = 455\); for math problems in Block 2, \(p = .03\), for tempting media in Block 2, \(p = .02\)). (Note also that Simmons et al., 2011, recommend attempting precise replications when a study requires decisions about exclusion of data, something that we did with the two samples in Study 4).

**Supplementary analyses.** Here we report a number of additional analyses of data from the “diligence task.” These support the same overall conclusion emphasized in the manuscript.

First, we found that the primary effect of the purpose intervention—a condition difference on Block 2—was significant when treating as missing data participants who failed to engage at all in Block 2, \(t(276) = 2.88, p = .004\), rather than coding them as having completed zero problems as in the analysis presented above.

Next, we re-conducted analyses a negative binomial model rather than OLS, so as to account for the large number of zeroes in the dependent variable. When doing this there was again a significant main effect of the purpose intervention compared to control in Block 2.

Third, the same overall conclusion that a self-transcendent purpose improved self-regulation were supported when we analyzed the number of tempting videos or video games played, instead of number of math problems solved. In Block 2 there was a highly statistically significant difference between the purpose and control conditions, \(b = -.40, t(281) = -2.88, p = .004, d = .34\), and this effect was significant in Sample 1, \(t(99) = 2.06, p = .04, d = .41\), and Sample 2, \(t(178) = -2.27, p = .02, d = .34\), and was no different across samples, interaction \(t(276) = 0.03, p = .98\).

**Pilot Study for Study 2:**

**Assessing Immediate Effects of the Purpose Manipulation on Meaningfulness of Schoolwork**

In the text of Study 2, we reported a pilot test of the effect of the purpose manipulation on the measure of the meaningfulness of schoolwork, which is a modified version of the Behavioral Identification Form (Vallacher & Wegner, 1989). While we report the contrast between the purpose intervention and the control in the text, this study also included a third, self-oriented condition that parallels Study 4 in the text. Here we report the full analyses of these data, as well as an exploratory moderation analysis.

**Participants.** Participants were \(N = 451\) high school students from 13 different high schools across the country whose teachers asked to participate in our research. Nineteen percent of the students were Asian, 7% were African American, 28% were Hispanic / Latino, 29% were White, and 17% self-identified as “other.” The high schools were diverse: eight were public district schools, four were public charter schools, and one was a private school. Schools varied widely in
socioeconomic characteristics; in five schools, 0-10% of students received free or reduced lunch because of their low household income; in two schools the figure was 11-50%; and in the remaining six schools, more than half of students were from low-income households. High school students were used as participants in the present study in order to speak more directly to the experimental effects on STEM-course GPA demonstrated in Study 2.

**Procedure.** Experimental procedures closely mirrored those in Study 2. The study consisted of two survey sessions spaced approximately two weeks apart (\( M = 13 \) days), some time in January or February. During the school day, teachers directed students to a website (www.perts.net) that delivered the two sessions. In the first session, participants completed a baseline survey assessing overall interest in school. In the second session, participants completed the manipulation materials, followed by an extended version of the meaningfulness of schoolwork items described in Study 1.

As noted, there were three experimental conditions: the control condition used in Study 2 in the text, the purpose condition used in Study 2 in the text, and a version of the self-oriented condition used on Study 4 in the text.

Considerable precaution was taken to prevent demand effects or experimenter influence. Teachers presented the experience as a survey, not an intervention; no mention was made to students that the purpose writing materials were designed to affect their thinking or behavior; and no teacher at the school had access to the materials or was aware of students’ random assignment to condition. Researchers never interacted with students.

**Measure of meaningfulness of schoolwork.** Meaningfulness of schoolwork was measured immediately after the manipulation (see Study 1 for more detail; also see Figure 1 in the manuscript). We administered a 9-item measure that included additional behaviors that were similar to those described in Study 1 (e.g., copying math formulas off of the chalkboard). All of the items are reproduced at the end of this supplement. We summed across the items, with higher values corresponding to higher levels of construal (\( \alpha = .73 \)).

**Measure of interest in schoolwork.** To use in exploratory moderator analyses, we assessed students’ intrinsic interest in school on the baseline survey (see Hulleman & Harackiewicz, 2009). We asked students to indicate how true the following two statements were about them: “I think school is interesting.” and “I think what we're learning in classes is interesting.” Participants answered both items on 7-point scales (Response options: *Strongly disagree*, *Disagree*, *Slightly disagree*, *Neither agree nor disagree*, *Slightly agree*, *Agree*, *Strongly Agree*). We averaged across these items, with higher values corresponding to greater interest (\( \alpha = 80 \)).

**Results.** First, we report the findings that also appear in the text. In an OLS regression with two dummy variables (one indicating the purpose condition and the self-oriented condition), the purpose manipulation led to greater meaningfulness of schoolwork compared to the control, \( t(446) = 2.67, p = .007, d = .25 \) (Control raw \( M = 4.78, SD = 2.53 \) vs. Purpose raw \( M = 5.39, SD = 2.41 \)).
As our purpose for learning manipulation contained a large amount of self-oriented information that students were encouraged to connect to their self-transcendent aims, a secondary question was whether simply cueing students into thinking about intrinsic, self-oriented reasons for learning was sufficient to increase the meaningfulness of boring academic tasks. The self-oriented manipulation had no significant impact on students’ judgments of the meaningfulness of their schoolwork relative to control, $t(446) = 1.21, p = .22, d = .11$ (Self-oriented raw $M = 5.05$, $SD = 2.41$).

The self-oriented condition scored between the purpose and neutral control, as in Study 4. Comparisons between the self-oriented and purpose manipulations revealed that students’ levels of the meaningfulness of schoolwork in the two conditions did not significantly differ from one another, $t(446) = 1.20, p = .23$. This finding also mirrors Yeager et al.’s (2012) research, which showed that those with only a self-oriented motive for learning did not differ significantly from either group in terms of the meaningfulness of schoolwork.

Moderation by baseline interest in school. We explored whether the purpose manipulation might have the greatest effects on the meaningfulness of common school activities among students who reported that school overall was uninteresting. Consistent with our theory, in an OLS regression there was a significant Purpose manipulation (vs. neutral control) × Overall interest in school interaction, $b = -.37, t(451) = -2.71, p = .007, \beta = -.38$, such that uninterested students showed the greatest increases in level of the meaningfulness of schoolwork relative to controls. Although we conducted this test using a continuous variable, it is possible to illustrate this by conducting simple effects analyses within substantively meaningful sub-groups—that is, “interested” students (who “agreed” that school was interesting, i.e., average score over 5), and “bored” students (who did not “agree” that school was interesting i.e., average score of 5 or below). Simple effects analyses revealed that among “bored” students there was a significant effect of the self-transcendent purpose manipulation compared to controls, $b = 0.93, t(237) = 2.87, p = .004, d = .37$, but no effect compared to controls among “interested” students, $b = 0.06, t(214) = .17, p = .87, d = .02$. Thus, a purpose truly created meaning in the midst of boredom.

By contrast, the Self-oriented manipulation (vs. neutral control) × Overall interest in school interaction was non-significant, $b = -.17, t(451) = -0.90, p = .37, \beta = -.16$, and the self-oriented manipulation showed no effect compared to controls in either sub-group of baseline interest, $ps > .19$. However, simple effects analyses revealed a significant difference between the purpose and the self-oriented condition among “bored” students, $b = 1.07, t (237)=3.04, p = .003, d = .39$, and not among “interested” students, $b = .05, t(214)=0.13, p = .90, d = .02$. Thus, within the sub-group of “bored” students, the purpose condition differed significantly from the self-oriented group.

Summary. Altogether, the findings from this pilot study support the theoretical interpretation of the results reported in the manuscript. Specifically, (a) the purpose intervention altered the meaningfulness of schoolwork in the short term, as expected based on theory; (b) this was especially true among “bored” students, as expected based on theory; and (c) a highly similar self-oriented intervention was not sufficient to produce these benefits among disinterested students.
**A PURPOSE FOR LEARNING**

**Additional Text from the Purpose Intervention**

*Below we reproduce the exact text from most of the self-transcendent purpose intervention.*

In this part of the study, we are interested in learning more about your opinions about the world. [page break]

How could the world be a better place? Sometimes the world isn't fair, and so everyone thinks it could be better in one way or another. Some people want there to be less hunger, some want less prejudice, and others want less violence or disease. Other people want lots of other changes. What are some ways that you think the world could be a better place? Everything you write will be kept anonymous. [page break]

Thank you for sharing your thoughts. Next we would like to learn more about what kind of person you want to become. [page break]

**What do you want to get out of high school? What kind of person do you want to be?**

A scientific survey of high school students by Stanford University

When you were younger, other people made all your decisions for you. You weren't in charge of your future. But in high school, you start to take more responsibility for yourself and for your future – to decide what to do and why to do it. One choice students make is how hard to work and what to work hard on. Almost everyone tries hard in school at least sometimes, and we're trying to learn why students put in that extra effort. So we started surveying high school students.

The first thing most students talked about is wanting to make more money by getting a good job. But we also learned that money was hardly ever the only reason—or even the main reason—when they really thought about it.

Most students said they also work hard because of unique and personal reasons, even though they usually don't talk about them to friends. Some students hadn't even put these reasons into words until they took the survey. But when they thought about it, it was these more personal reasons that really helped them get through the hard days when homework piled up and life got crazy. And it was these personal reasons that helped them see that even day—to—day activities had a lot of meaning for their life overall.

This is what students said motivated them to work hard:

- 64% said they wanted to be an educated person who has something to intelligent to say about what's going on in the world.
- 59% said they want to learn so they can make a positive contribution to the world.
- 78% said they want to gain knowledge so that they can have a career that they personally enjoy.
- 72% said they want to have the freedom to pick the life that they want to live.
It's more interesting to hear this in students' own words. We picked three typical responses from normal students on the next few pages. Please read them, then we will ask if you could share your own thoughts.

[Students read quotations from former students who had completed the materials previously, edited by researchers; contact the authors for access to these]

Your turn: Why is learning important to your goals?

Our surveys are still in progress, and we would like students like you to be a part of the conversation.

Take a moment to think about what kind of person you want to be in the future. Also think about what kind of positive impact you want to have on the people around you or society in general. We're not asking about things like money, high status, or power – even though those things can be important. Instead, we want to know what knowledge and abilities you want to have, and why you want to have them.

Please take a few minutes to think about this and write your thoughts so they can be shared with others. Everything you write will be kept anonymous.

In the space below, write a few sentences that answer this question: How will learning in school help you be the kind of person you want to be or help you make the kind of impact you want on the people around you or society in general? (Don't worry about spelling or grammar. Just focus on getting your ideas across.)
Personal Meaningfulness of Schoolwork Measure

Using a planner to record upcoming tasks
